Mexico since April 1996. The data acquired with a 17.5 visual magnitude.

permits analysis of altitude, inclination, and size of debris for LEO. The only limiting factors of the detection range for the LMT are size a n d albedo. Approximately 401 hours were collected from October 1997 through January 1999 using microchannel plate with about a 0.42 degree field of view. In this data set, the LMT detection shows a falloff at a diameter of about 11 cm based existing radar data. See Figure 1. With microchannel this

object the LMT was capable of detecting was a NASA has been collecting and analyzing two-centimeter diameter object with an albedo data recorded through a 3-meter zenith staring of 0.1 (assuming a circular orbit) at an altitude liquid mirror telescope (LMT) located in New of 1000 kilometers; this equates to an object

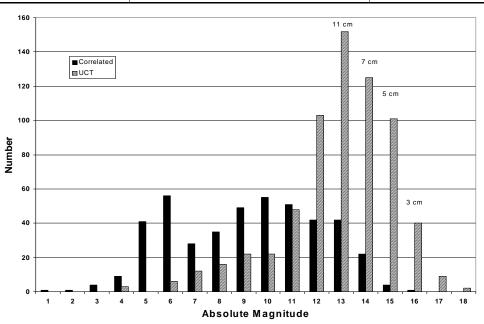

Figure 1. Absolute Magnitude Distribution for data from 10/97 to 01/99.

Out of 401 hours, the counts returned for objects seen were 389 correlated targets (CTs), 441 UCTs and 127 nosees. Of the CTs, 14% were seen on multiple nights meaning the number of unique CTs were 332. Of the

> nosees, 10% were duplicates. Using a duplicity average of 1 2 % + / -2 %, potentially 53 UCTs were repeat objects, indicating 388 unique UCTs have been observed. Assuming most of the objects down to 5 cm were seen and assuming a polynomial progression, analysis suggests that in LEO, conservative estimate of total untracked (altitude < 2000 km; debris size < 5 cm diameter) is 10,000 objects. Most of these objects fall into less-than-10-cm

LMT Data Reduction Continues, Continued

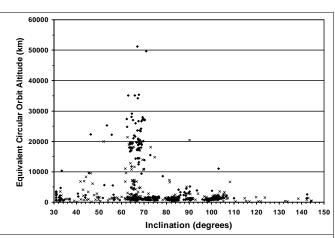

Figure 2. Data from 10/97 to 01/99. All detections to 60000 km are displayed. A 2 degree correction has been applied to the inclinations. The 2 degree bias in this data has since been reduced 0.5 degrees or less by applying a more accurate Earth model. Solid diamonds represent correlated targets while Xs represent UCTs.

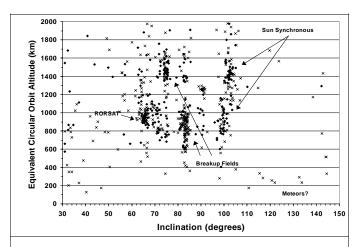

Figure 3. Data from 10/97 to 01/99. All detections to 2000 km are displayed. A 2 degree correction has been applied to the inclinations. A few of the general debris areas are identified. Solid diamonds represent correlated targets while Xs represent UCTs.

(Continued from page 1)

The microchannel plate suffered a failure in January 1999 and a new microchannel plate with a smaller field of view (~.24 degrees) but higher sensitivity came on line in March of 1999. To date, about 240 hours have been collected. Of those, about 130 hours have been reduced and are undergoing analysis. Because the shadow height limits viewing time at lower elevations, the actual observation hours at the lower elevations are not 130 hours. Data

reduction of the other 110 hours will proceed leaving 321 unique objects. A falloff at a shortly.

plate Preliminary results of the 130 hours of data indicate that the LMT has found 341 uncorrelated targets and 101 correlated targets for a total of 442 objects seen. Of the correlated targets, 6 have been duplicates; this is reasonable when compared with the previous data as the new field of view has a smaller viewing area. Assuming ~6% duplicity, 20 of Data

leaving 321 unique objects. A falloff at a diameter of about 11 cm occurs with this data as well. See Figure 4. This may indicate a limiting factor of detection or may imply characteristics of the orbital debris environment. As the data only represent half the number seen in the 97-99 data set and analysis is still preliminary, any conclusion would be premature.

(Continued on page 3)

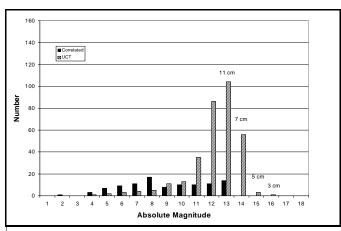

Figure 4. Absolute Magnitude Distribution for data from 03/99 to 11/99.

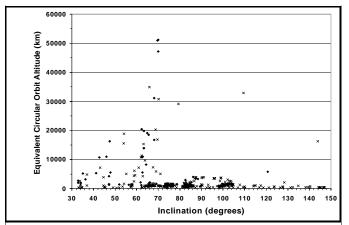

Figure 5. Data from 03/99 to 11/99. All detections to 60000 km are displayed. Inclination error is 0.5 degrees or less. Solid diamonds represent correlated targets while X's represent UCTs.

MT Data Reduction Continues, Continued

(Continued from page 2)

For figures 2, 3, 5 and 6, objects below 500 km may well be meteors but as the objects are outside of the Earth's shadow, this cannot be confirmed. For figures 3 and 6, a few general groupings are listed such as RORSAT and SPOT. The breakup fields show a high number of UCTs, as would be expected. In Figure 6, sun synchronous, RORSAT, and the breakup fields are already becoming easily recognizable groupings, and few UCTs and no correlated targets have been found in the "SPOT" area.

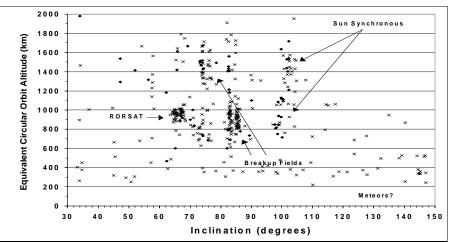

Figure 6. Data from 03/99 to 11/99. All detections to 2000 km are displayed. Inclination error is 0.5 degrees or less. Solid diamonds represent correlated targets while Xs represent UCTs.

Compton Gamma Ray Observatory Successfully Deorbited

Compton Gamma Ray Observatory (CGRO) was successfully deorbited over the eastern Pacific Ocean on 4 June. The 5-day maneuvering sequence to bring CGRO down from its 510 km circular orbit was flawlessly executed by the spacecraft control team at the Goddard Space Flight Center. In addition, a joint NASA JSC - Department of Defense operation to collect valuable reentry breakup data was accomplished.

The decision to initiate the long-planned deorbiting of the nearly 14 metric ton (dry mass) spacecraft was prompted by the failure in December 1999 of one of three gyroscopes (Orbital Debris Quarterly News, January 2000, pp. 6-7). To avoid taking a calculated risk of 1 in 1,000 that someone in the world might be reentry in an uninhabited, broad ocean area was The early June reentry date was advantageous both for the spacecraft power

announcement by NASA Headquarters, the for observing the reentry with airborne optical i.e., placing CGRO on a reentry trajectory. and infra-red sensors.

> A series of very small engineering maneuvers, lasting less than a total of 4 seconds, was performed on 27 May, verifying that all thrusters were operational and ready for the four large maneuvers which would be needed to deorbit CGRO. The first major burn occurred early on 31 May, lasted 23 minutes, and resulted in lowering the perigee of CGRO to 364 km. A second, 26-minute burn was conducted about 25 hours later, lowering perigee to 250 km.

> Burns 3 and 4 were scheduled about an hour and half apart early on 4 June. The nearly was non-nominal. The fourth and final burn commenced at 0522 UTC on 4 June and lasted

accordance with a 24 March system (due to orbital lighting conditions) and for 30 minutes, dropping perigee to only 50 km,

Attitude control of the spacecraft was maintained until 0609 UTC, followed by loss of communications at 0610. The breakup of CGRO probably began about one minute later at an altitude of 78 km near the location of 14.7 N, 127.7 W. The estimated 6 metric tons of surviving debris should have impacted the ocean starting about 600 km downrange of the reentry point and extending for more than 600 km beyond that point.

At the time of reentry a U.S. Air Force aircraft was deployed over the Pacific Ocean to train its optical and infra-red sensors along the reentrying spacecraft's trajectory. The precise 22-minute Burn 3 reduced CGRO's perigee to performance of the reentry maneuvers placed about 150 km, the minimum altitude considered CGRO at exactly the predicted location and safe to ensure survival of the spacecraft for at time, enabling the aircraft to perform its injured by falling debris, a precisely controlled least 24 hours. This strategy allowed time to mission with great success. NASA and the implement contingency procedures if Burn 3 Department of Defense will examine the collected data and compare it with model predictions.

Reexamining GEO Breakups

Recent searches for orbital debris at GEO known and hypothesized satellite breakups near altitudes by NASA and ESA, in support of an action item of the Inter-Agency Space Debris Coordination Committee (IADC), have revealed been confirmed. The first subject, the Ekran 2 a significant population of uncataloged objects. To assess these data more completely, NASA's malfunction on 23 June 1978. Three new debris Orbital Debris Program Office has reviewed were observed, but none have been cataloged.

the GEO regime.

To date, only two breakups near GEO have spacecraft, suffered a catastrophic battery

On 21 February 1992, 22 debris from a Titan Transtage (1968-081E) were observed, apparently only one-half hour after a fragmentation event.

The latter breakup was accompanied by a distinct, albeit slight, orbital perturbation. At (Continued on page 4)

Reexamining GEO Breakups, Continued

(Continued from page 3)

least four other Transtages (two below GEO and two above GEO) have also exhibited discrete orbital perturbations after many years in orbit. A hypothetical debris cloud was simulated for one of these four vehicles (1966-053J), propagated to January 2000, and compared with the observed uncataloged objects. correlation was found, suggesting that no large debris (>20 cm) were created at the time of the orbital perturbation. Similar analyses are planned for the other three Transtages, and more sophisticated debris searches are being considered.

As many as 20 other GEO satellites (18 Soviet/Russian, 1 Japanese, and 1 Italian) have been suggested as possible breakup candidates

based solely on orbital perturbations. However, these perturbations, if real, are the result of changes in velocity of much less than 1 m/s. Such a change is much smaller than normally associated with a breakup event, either by explosion or collision, and could be induced by other mechanisms.

The NASA study has identified a LEO precedent of orbital perturbations not unlike those seen with the Titan Transtages. Over 100 of the more than 400 Comos 3M second stages placed in LEO have exhibited significant orbital perturbations, some as long as 10 years after launch. Most of the events represent a single impulse, but several vehicles clearly experienced multiple small impulses over many days or weeks. In only one case (1991-009J)

were these orbital perturbations linked to debris production events. The cause of these orbital perturbations is believed to be the venting of residual propellants - the same propellants as used by the Titan Transtages.

The preliminary results of this study were presented at the 18th meeting of the IADC in June. A more comprehensive summary will be presented next year after the work has been completed. Although some of the observed uncataloged debris in GEO may have originated satellite breakups, simple orbital perturbations alone may be insufficient evidence. Other debris sources should also be considered.

The Pitfalls of a Poor Random Number Generator in Monte Carlo Orbital Debris Models

D. T. Hall

algorithms can potentially introduce significant objects dominate the exploding population in collision probability, Q_c , is the expected number inaccuracies in Monte Carlo projections of EVOLVE simulations. However, almost half of of collisions per time-step per volume element orbital debris populations. In the NASA EVOLVE 4.0 orbital debris model, using a flawed random number generator (of the type commonly provided on many commercial computer systems) can artificially skew explosion rates by a few percent, and can bias collision rates by 40% or more.

The most basic component of any Monte Carlo calculation is the random number generator that, ideally, produces a completely random sequence of numbers distributed uniformly over the interval 0 to 1. In a Monte Carlo simulation, each random number, R, is used to help make a decision. For instance, the EVOLVE orbital debris model uses random numbers to help decide when an unstable rocket-body might explode, or when an on-orbit collision might occur. Recent analysis has shown that it is critical for the random number generator used in the EVOLVE calculation to be robust in the limit of small values of R as well as in the limit of small values of the quantity 1 - R.

Explosions are generated in the EVOLVE simulation by comparing a random number, R, to the probability that each object will explode sometime during its orbital lifetime, P_{ex} . If R < P_{ex} , then the object explodes in the simulation and an appropriate debris cloud is added to the orbiting population. Most orbiting objects are classified as non-explosive and have $P_{ex} = 0$.

Explosion probabilities for discarded rocket can bias collision rates much more than all explosive objects in EVOLVE have $P_{ex} \approx 7 \text{ x}$ 10^{-4} . This class includes spacecraft with moderately unstable components such as batteries or depleted propellant tanks. For the correct number of explosions to occur in this special class, the random number algorithm must generate a uniform sequence in the range $R \le 7 \times 10^{-4}$. Our analysis indicates that some common random number generation algorithms fail in this regard (i.e., produce too many or too few values with $R \le 7 \times 10^{-4}$) and can potentially skew explosion rates for this class of object by about 2.5%.

In addition to explosions, EVOLVE must calculate the expected number of on-orbit collisions per time-step per volume-element per particle size-bin, defined here as Q_c . Because debris collisions are rare events, most values of Q_c calculated by EVOLVE are very small numbers, much less than one. In this case, Q_c is more intuitively regarded as the probability of a collision occurring, and typical values span the range $10^{-9} \le Q_c \le 10^{-3}$. Collisions are generated in EVOLVE simulations by comparing Q_c to the quantity, 1-R, where R is produced by a random number generator. If $1-R < Q_c$, then a collision occurs in the simulation and the two colliding objects break-up and generate a debris cloud. Because probabilities for on-orbit collisions can be so much smaller than for explosions, a flawed random number algorithm

Flaws in random number generation bodies span the range 10^{-2} to 10^{-1} , and these explosion rates. In addition, because the per particle size-bin, collision-rate inaccuracies introduced by a flawed random number generator will depend on the time-step, the size of volume elements and the width of each sizebin used in the calculation. For instance, when using the nominal 50 km altitude spacing to define volume elements, a commonly-employed flawed random number generator can bias EVOLVE collision rates by up to 40%. For 10 km altitude spacing, such inaccuracies can grow up to 250%, demonstrating that that a faulty random number generator may introduce a very large, non-linear bias in orbital debris collision rates.

To avoid these pitfalls, it is particularly important for Monte Carlo orbital debris models to employ robust random number generators. NASA's EVOLVE 4.0 model employs the random number function RAN2 given in the "Numerical Recipes" compendium (W. H. Press et al., 1989, Cambridge University Press). Testing indicates that this algorithm generates uniformly distributed random number sequences down to the limit where either R or 1 - R approach values as small as 10^{-10} , ensuring accurate calculation of on-orbit explosion and collision rates in orbital debris projection calculations.

Space debris, in particular, artificial debris or man-made refuse, poses a threat to human space flight and robotic missions in Earth orbit. To date, most attention to debris risks has been given to human space flight operations which require high levels of reliability and safety and involve vehicles which are typically much larger than robotic spacecraft. However, the artificial debris flux already exceeds that of the natural meteoroid environment for many important orbital regimes.

The degree of risk from artificial debris is dependent upon the size and construction of the

satellite, the orbital characteristics, and the implications for future space missions. length of time that the satellite will remain in environment may be quite dynamic due to solar cycle effects, satellite fragmentations, the use of solid-propellant upper stages, spacecraft operations or malfunctions, and satellite surface degradations. Consequently, the consideration of potential space debris effects is now warranted in the early design phase for most space missions. Such assessments not only evaluate the effect of the space environment on the satellite mission, but also the effect of the satellite mission on the environment, including

Within NASA and the U.S. Government, In addition, the artificial debris guidelines and standard practices for debris mitigation have been developed. Mitigation measures can range from spacecraft and upper stage design and operational changes to mission orbit selection and disposal options. International recognition of these issues is also improving, as evidenced by the growth in membership of the Inter-Agency Space Debris Coordination Committee and the inclusion of space debris as a regular agenda item at the United Nations.
